

CHAPTER 6

Designing Classes

You don't understand. I coulda had class. . . .

—Marlon Brando's character in
On the Waterfront, 1954

[6.1 Representing points](#)

[6.2 Operator overloading](#)

[6.3 Rational numbers](#)

[6.4 Designing a token scanner class](#)

[6.5 Encapsulating programs as classes](#)

Data Types in C++

- Primitive types include but not limited to:

int	This type is used to represent integers, which are whole numbers such as 17 or -53.
double	This type is used to represent numbers that include a decimal fraction, such as 3.14159265.
bool	This type represents a logical value (true or false).
char	This type represents a single ASCII character.

- Collections/Containers
- Compound data types:
 - Enumerated types
 - Structures
 - Classes (e.g., C++ strings and streams)

Enumerated types

- An enumerated type can be roughly considered as a subset of `int` with special names for each value in the subset:

```
enum class Direction { NORTH, EAST, SOUTH, WEST };
```

- When the C++ compiler encounters this definition, it assigns values to the constant names by numbering them consecutively starting with 0. Thus, NORTH is assigned the value 0, EAST is 1, SOUTH is 2, and WEST is 3.
- You can assign values by yourself:

```
enum class Coin {  
    PENNY = 1,  
    NICKEL = 5,  
    DIME = 10,  
    QUARTER = 25,  
    HALF_DOLLAR = 50,  
    DOLLAR = 100  
};
```

Enum - Example

```
const int PieceTypeKing { 0 };  
const int PieceTypeQueen { 1 };  
const int PieceTypeRook { 2 };  
const int PieceTypePawn { 3 };  
//etc.  
int myPiece { PieceTypeKing };
```

VS

```
enum class PieceType { King, Queen, Rook, Pawn };
```

```
PieceType piece { PieceType::King };
```

```
if (PieceType::Queen == 2) { ... }...
```

Not
allowed

Note: old-style enum

- as integers, not strongly-typed
 - Catch: compare one enum type with another (not practical)
- values must be unique

```
bool ok;  
enum status { ok, done }
```

- values are exported (enclosing scope)

```
enum state { idle, running, unknown }  
enum error { none, memory, disk, unknown }
```

Structures

- All modern higher-level languages offer some facility for representing **structures**, which are **compound** values in which the individual components are specified by name.
- Given that C++ is a superset of the older C language, it is still possible to define classic C structures, which are defined using the following syntactic form:

```
struct typename {  
    declarations of fields  
};
```

- **This definition creates a *type*, not a *variable*.** If you want to declare variables of the structure type, you use the type name just as you would with any other declaration.

Representing Points

- One of the simplest examples of a data structure is a *point*, which is composed of an x coordinate and a y coordinate component.
- C++ offers more than one model for representing a point value. The older style, which C++ inherits from C, is to define the `Point` type as a *structure*. The more modern approach is to define `Point` as a *class*. The next several slides explore each of these models.

Representing Points Using a Structure

- For most graphical devices, coordinates are measured in pixels on the screen, which means that these components *x* and *y* should be integers, since it is impossible to illuminate a fraction of a pixel.

```
struct Point {  
    int x;  
    int y;  
};
```

- This definition allows you to declare a **Point** *variable* like this:

```
Point pt;
```

- Given the variable **pt**, you can select the individual *fields* or *members* using the dot operator (**.**), as in **pt.x** and **pt.y**.

Representing Points Using a Class

- Although structure types are part of the history of C++ and the languages that came before it, they have largely been supplanted by classes, which offer greater power and flexibility. The `Point` structure from the preceding section is identical to the following class definition:

```
class Point {  
public:  
    int x;  
    int y;  
};
```

- This definition allows you to declare a `Point` **object** like this:

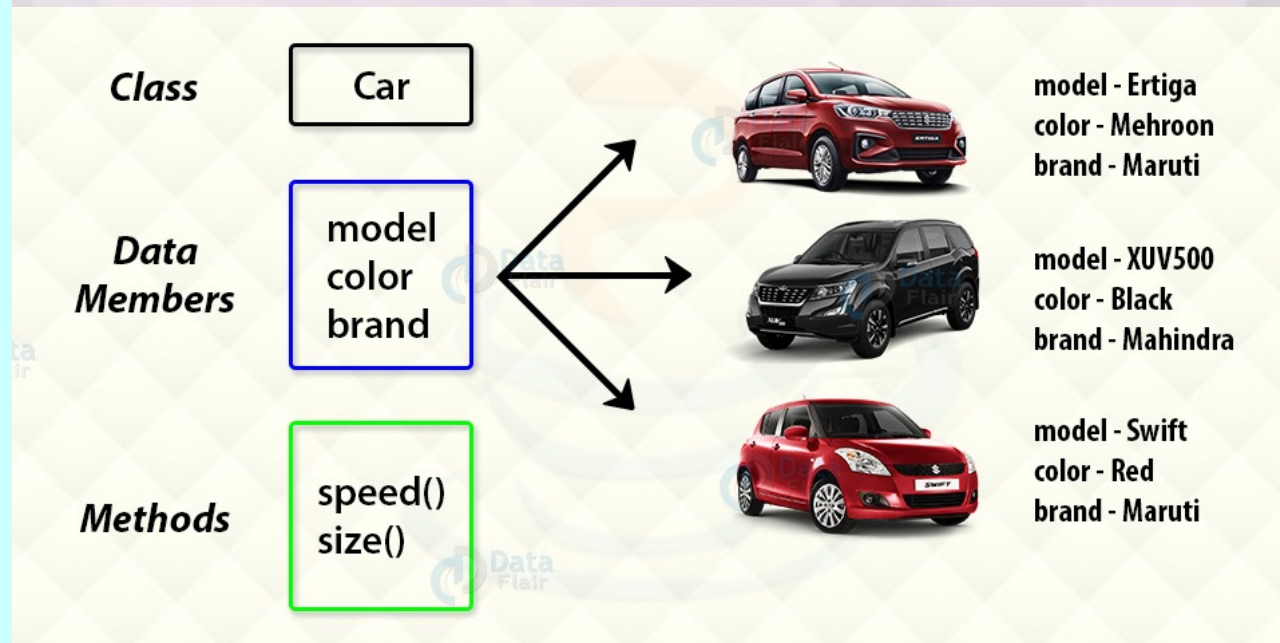

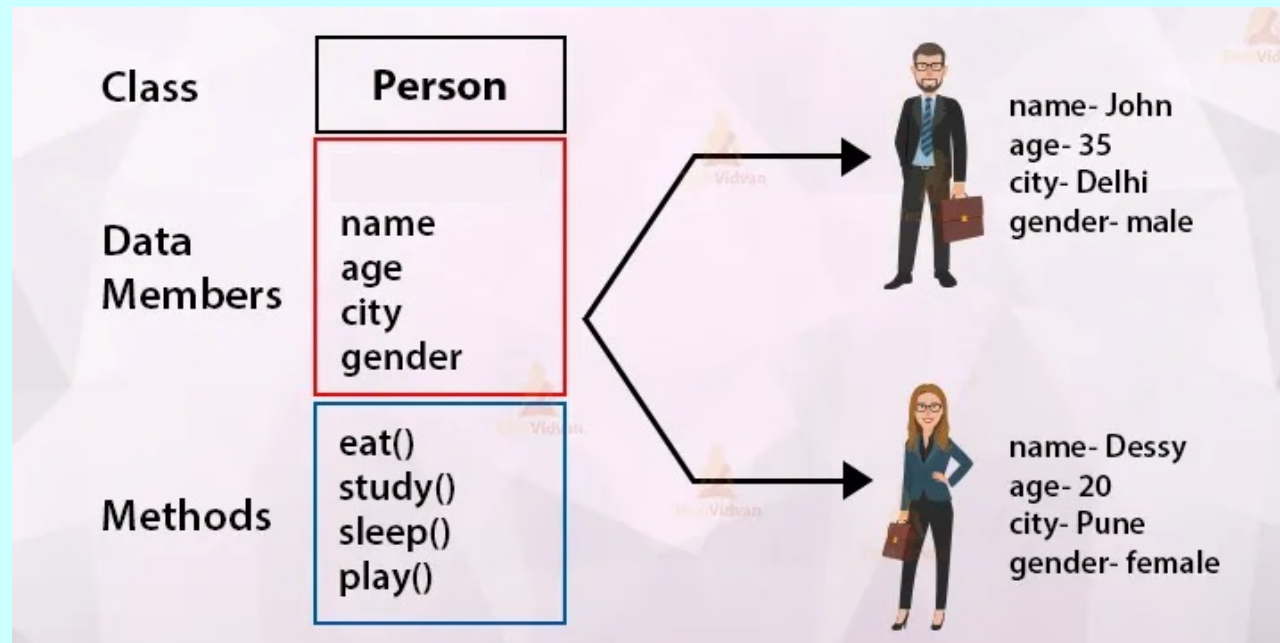

```
Point pt;
```

- As the `x` and `y` fields are included as part of the `public` section, which is visible to clients, you can select the public **fields** using the dot operator (`.`), as in `pt.x` and `pt.y`.

Classes and Objects

- In C, **structures** define the **representation** of a compound value, while **functions** define **operations** on these data. In C++, these two ideas are **integrated**.
- Object-oriented languages are characterized by representing most data structures as **objects** that encapsulate both the representation and the behavior of the objects (i.e., operations on the data) in a single entity.
- As in Python, the C++ object model is based on the idea of a **class**, which is a template describing all objects of a particular type. The class definition specifies the representation of the object by naming its **fields** or **instance variables** (e.g., compound property/attribute values) and the behavior of the object by providing a set of **methods**.
- New objects are created as **instances** of a particular class, and the creation of new instances is called **instantiation**.

Class and Objects

```
class Person {  
    public:  
        // methods  
        void eat();  
        void study();  
        void sleep();  
        void play();  
  
        // data  
        string name;  
        int age;  
        string city;  
        char gender;  
}
```

```
Person p;  
  
p.name = "mike"s;  
p.age = 18;  
p.city = "toronto"s;  
p.gender = 'm';
```

The Imperative Programming Paradigm

Flashback

- **Imperative** programming paradigm: an explicit sequence of statements that change a program's state, specifying **how** to achieve the result.
 - **Structured**: Programs have clean, **goto**-free, nested **control structures**.
 - **Procedural**: Imperative programming with **procedures** operating on data.
 - **Object-Oriented**: Objects have/combine **states/data** and **behavior/methods**; Computation is effected by **sending messages to objects (receivers)**.
 - **Class-based**: Objects get their states and behavior based on membership in a class.
 - **Prototype-based**: Objects get their behavior from a prototype object.

Class Construction - Life Cycle

- Class Definition (data, methods)
- Class Implementation
- Access Control (public, private, protected,...)
- Object Construction & Destruction
- Data member initialization
- Using the objects
- Copy & Assignment
- Operator Overloading (==, +=, >, <, ...)
- Inheritance & polymorphism

The Format of a Class Definition

- In C++, the definition of a class typically looks like this:

```
class typename {  
    public:  
        prototypes of public methods  
  
    private:  
        declarations of private instance variables  
        prototypes of private methods  
};
```

- The entries in a class definition are divided into two categories:
 - A **public** section available to clients of the class
 - A **private** section restricted to the implementation

Other Access
Specifier:
protected, friend

Representing Points Using a Class

- Declaring public instance variables, however, is discouraged in modern object-oriented programming. Today, the common practice is to make all instance variables **private**, which means that clients have no direct access to the internal variables.
- Clients instead use methods exported by the class to obtain access to any information the class contains. Keeping implementation details away from the client is likely to foster *simplicity*, *flexibility*, and *security*, as described in the previous lectures.

Access
Specifier

```
class Point {  
public:  
    prototypes of public methods to access x and y  
private:  
    int x;  
    int y;  
};
```

Rule of thumbs - Encapsulation

- When deriving a class, it's best to keep all data members private to provide the highest level of encapsulation.
- You can change how you represent your data while keeping the public and protected interfaces unchanged.

Implementing Methods

- A class definition usually appears as a `.h` file that defines the *interface* for that class. The **class definition** does not specify the implementation of the methods exported by the class; only the prototypes appear.
- Before you can compile and execute a program that contains class definitions, you must provide the implementation for each of its methods. Although **methods can be implemented within the class definition**, it is stylistically preferable to define a **separate .cpp file** that hides those details. In some rare cases, however, some simple implementations can be included in the `.h` file, therefore a `.cpp` file is not always required.
- Method definitions are written in exactly the same form as traditional function definitions. The only difference is that you write the name of the class before the name of the method, separated by a double colon. E.g., the `Point` class exports a `toString` method, you would code the implementation using the method name **`Point::toString`**. (\approx `__str__` in Python)

Class Definition

```
public:

    // constructor
    Point();    // default (no parameter)
    • Point(int xc, int yc);

    // getters
    int getX() const &;    // instance only
    int getY() const &;    // instance only
```

Method Implementation

```
// getters
int Point::getX() const & { return x; }
int Point::getY() const & { return y; }
```

Getters and Setters

- In computer science, methods that retrieve the values of instance variables are formally called *accessors*, but are more often known as *getters*. By convention, the name of a getter method begins with the prefix `get` followed by the name of the field after capitalizing the first letter in its name. The getters for the `Point` class can therefore be defined as `getX` and `getY`.
- Methods that set the values of specific instance variables are called *mutators* or, more informally, *setters*. If the `Point` class were to export a `setX` and a `setY` method that allowed the client to change the values of these fields, you could easily replace any application that previously used the old structure type with a version that relies entirely on the new `Point` class.
- Remember the *getters* and *setters* in the collection classes?

```

class Person {

    public:

        // methods
        void eat();
        void study();
        void sleep();
        void play();

        // Setters
        void setName(string name) { this->name = move(name); }
        void setAge(int age) { this->age = age; }
        void setCity(string city) { this->city = move(city); }
        void setGender(char gender) { this->gender = gender; }

    private:
        // data
        string name;
        int age;
        string city;
        char gender;
};

```

```

Person p;

```

```

// p.name = "mike"s;
// p.age = 18;
// p.city = "toronto"s;
// p.gender = 'm';

```

```

p.setName("mike"s);
p.setAge(18);
p.setCity("toronto"s);
p.setGender('m');

```

Setters or not?

- It is, however, counter-intuitive to add setter methods to a class after deciding to make its instance variables private, because part of the reason for making them private is to ensure that clients don't have **unrestricted access** to them.
- In general, it is considerably safer to allow clients to *read* the values of the instance variables than to *write* those values. As a result, **setter methods are far less common than getters in object-oriented design.**
- Many classes are designed in an even higher level of security by making it impossible to change the values of any instance variables after an object has been created (i.e., **immutable**). Although it is still possible to change the contents of an object by assigning another object to it, there is no way to change the individual fields in such an object independently. (Remember Python strings?)

Constructors

- In addition to method prototypes, class definitions typically include one or more **constructors**, which are used to **initialize** an object. (Remember `__init__()` in Python?)
- The prototype for a constructor **has no return type** and always **has the same name as the class**. It may or may not take arguments, and a single class can have **multiple constructors** (i.e., overloading) as long as the constructors have different signatures.
- The constructor that takes no arguments is called the **default constructor**. If you don't define any constructors, C++ will automatically generate a default constructor with an empty body.
- The constructor for a class is **always** called when you create an instance of that class, even if you simply declare a variable. The version being called is determined by the arguments.

Initializer List

- An *initializer list* is sometimes used in initializing the data members of a class. The initializer list appears just before the brace that begins the body of the constructor and is set off from the parameter list by a colon. The elements of the initializer list should be in one of the following forms:
 - The name of a field in the class, followed by an initializer for that field enclosed in parentheses.
 - A superclass constructor (will be discussed later with *inheritance*).

Initializer List

- The following example of initialization by assignments

```
Point(int xc = 0, int yc = 0) {  
    x = xc;  
    y = yc;  
}
```

can be optimized for efficiency by using the initializer list:

```
Point(int xc = 0, int yc = 0) : x(xc), y(yc) {}
```

- Using assignments, the members are initialized with default values, and then reassigned in the constructor body.
- Using the initializer list, the members are created and initialized only once, with the given value.
- **Constant members** can only be initialized using the initializer list, because assigning a value to a constant is not allowed.

Constructors & Constructor Initializer

```
class Person {  
    public:  
        // Constructor  
        Person() = default;  
        Person(string na, int ag, string ci, char ge):  
            name(move(na)), age(ag),  
            city(move(ci)), gender(ge) {}  
  
        // methods  
        void eat();  
        void study();  
        void sleep();  
        void play();  
  
        // Setters  
        void setName(string name) { this->name = move(name); }  
        void setAge(int age) { this->age = age; }  
        void setCity(string city) { this->city = move(city); }  
        void setGender(char gender) { this->gender = gender; }  
  
    private:  
        // data  
        string name;  
        int age;  
        string city;  
        char gender;  
};
```

```
Person p1 {"mike"s, 18, "toronto"s, 'm'};  
Person p2;
```

```
p2.setName("mike"s);  
p2.setAge(18);  
p2.setCity("toronto"s);  
p2.setGender('m');
```

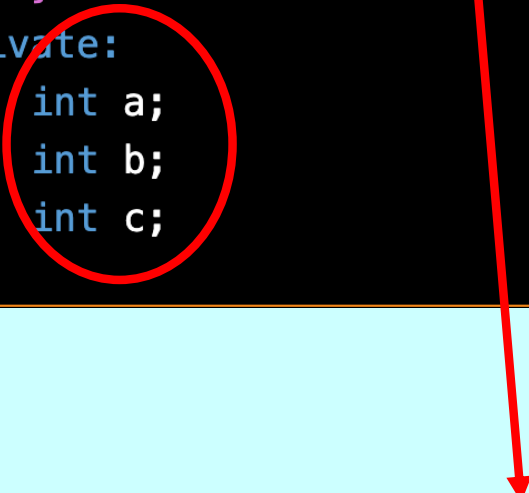

Note: Constructor_INITIALIZER

- data members are initialized in their **declared order** in the class definition, not their order in the constructor-initializer list, see example in next slide !!!
- Note the 3 variables (a,b,c) declared in the class, and their orders, plus the sequence of the variables in the constructor-initializer list.

```

class Construct {
public:
    Construct(int v1, int v2, int v3):
        // a(v1), b(v2), c(a+b) {
        c(v1), b(v2), a(b+c) { // compile warning
        cout << "Construct():" << a << "," << b << "," << c << endl;
        }
private:
    int a;
    int b;
    int c;
};

```

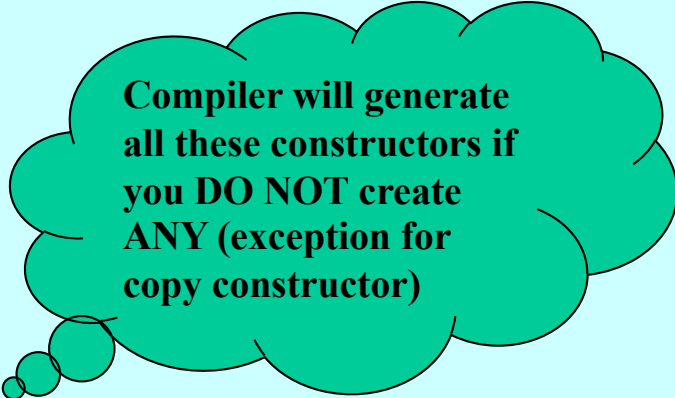

```

warning: field 'b' is uninitialized when used here [-Wuninitialized]
    c(v1), b(v2), a(b+c) { // compile error
                  ^
warning: field 'c' is uninitialized when used here [-Wuninitialized]
    c(v1), b(v2), a(b+c) { // compile error
                  ^

```

Note: Constructor

- `class foo {.....};`
- Default Constructor (`foo c1`, **not `foo c1()`**)
- Copy Constructor (`foo c2(c1)`, `foo c2 = c1`)
- Copy Assignment Constructor (`c2 = c1`)
- Move Constructor (`c2(move(c1))`, `c2(foo { })`)
- Move Assignment Constructor (`c2 = move(c1)`)

Compiler will generate all these constructors if you **DO NOT** create **ANY** (exception for copy constructor)

Compiler-generated Copy constructor

```
classname::classname(const classname& src)
    : m1 { src.m1 }, m2 { src.m2 }, ... mn { src.mn } { }
```

Copy vs Move Constructor

- Copy deals with lvalue or named variable
- Move deals with temporary objects
- Ex: Assignment statement, object creation, calling a function:
 - `string a {"hello"}`
 - `string b = a`
 - `string c = a + " world"s`
 - `foo(a)`

```

void print(string str){
|   cout << str << endl;
|   }

void print(string & str){
|   cout << str << endl;
|   }

void print(string && str){
|   cout << str << endl;
|   }

```

Ambiguous !
Call-by-value or
Call-by-reference ?

```

string a {"hello"s};
print(a);
print( "hello"s );

```

```

void printCopy(string str){
|   cout << str << endl;
|   }

void print(string & str){
|   cout << str << endl;
|   }

void print(string && str){
|   cout << str << endl;
|   }

```

Call-by-value

Call-by-reference

Call-by-move (temp. obj)

```

string a {"hello"s};
printCopy(a);

print(a);

print( "hello"s );

```

Constructor calls

vector of some object

```

class Cell {

public:
    // constructor
    Cell() = default;

    // normal
    Cell(int sz): m_sz(sz) {
        cout << "normal " << sz << endl;
        create(sz);
    }

private:

    int m_sz {0};
    int *m_ptr { nullptr };

};

```

Refer to the source
code for the
implementation of all
the different
constructors

```

Cell createCell() {
    return Cell {11};
}

void foo0() {

    vector<Cell> vec;

    // vec.reserve(10);

    for (int i {100}; i < 103; ++i) {
        cout << "Loop=" << i << endl;
        vec.push_back( Cell {i} );
        cout << endl;
    }

    Cell c1 {10};
    cout << endl;

    c1 = createCell();
    cout << endl;

    Cell c2 {12};
    cout << endl;

    c2 = c1;
    cout << endl;

}

```

Constructor Label

- “normal” = normal constructor, cell(5)
- “copy” = copy constructor, cellB(cellA)
- “copy=” = copy assignment , cellB = cellA
- “move” = move constructor, move(cellA)
- “move=” = move assignment, cellB = foo()

```

Cell createCell() {
    return Cell {11};
}

void foo0() {

    vector<Cell> vec;

    // vec.reserve(10);

    for (int i {100}; i < 103; ++i) {
        cout << "Loop=" << i << endl;
        vec.push_back( Cell {i} );
        cout << endl;
    }

    Cell c1 {10};
    cout << endl;

    c1 = createCell();
    cout << endl;

    Cell c2 {12};
    cout << endl;

    c2 = c1;
    cout << endl;
}

```

```

```

```
// copy constructor
Cell(const Cell & src): Cell(src.m_sz) {
    cout << "copy " << src.m_sz << endl;
    create(src.m_sz);
}

// copy assignment
Cell & operator=(const Cell & rhs) {
    cout << "copy= " << rhs.m_sz << endl;
    Cell tmp {rhs};
    swapFields(tmp);
    return *this;
}

// move constructor
Cell(Cell && src) {
    cout << "move " << src.m_sz << endl;
    swapFields(src);
}

// move assignment
Cell & operator=(Cell && rhs) {
    cout << "move= " << rhs.m_sz << endl;
    swapFields(rhs);
    return *this;
}
```

**Delegating to
normal
constructor**

Overloading Operators

- Besides *methods*, you can also implement some useful *operators*, even those existing ones in C++.
- One of the most powerful features of C++ is *the ability to extend the existing operators* so that they apply to new types. Each operator is associated with a name that usually consists of the keyword **operator** followed by the operator symbol.
- For instance, one of the most useful operators to overload is the insertion operator `<<`, which makes it easy to display values of that class on an output stream.
- We can use the following line:

```
cout << "(" << pt.getX() << "," << pt.getY() << ");";
```

or define a string representation of the object:

```
cout << pt.toString(); // ~ print(pt.__str__()) in Python
```

but it would be better if we could just:

```
cout << pt; // ~ print(pt) in Python
```

```
// getters
int getX() const &;           // instance only
int getY() const &;           // instance only

int getX() const &&;           // temporary only
int getY() const && = delete;  // prohibit temporary

// other public function
std::string toString();
```

```
// getters
int Point::getX() const & { return x; }
int Point::getY() const & { return y; }

int Point::getX() const && { return x; }

// other public methods
string Point::toString() {
|   return "("s + to_string(x) + ","s + to_string(y) + ")";
}
}
```

Overloading Operators

- The prototype and implementation for the overloaded << in the `Point` class is:

```
// Operator overloading (GLOBAL)
ostream & operator<<(ostream & os, Point pt) {
|   return os << pt.toString();
}
```

- Since stream variables cannot be copied, the `ostream` argument must be passed **by reference**.
- The << operator has a chaining behavior of returning the output stream, therefore, the definition of `operator<<` must also return its result **by reference**.
- Other operators that can be overloaded:

any of the following operators: + - * / % ^ & | ~ ! = < > +
|= << >> >>= <<= == != <= >= <=> (since C++20) && || ++

Overloading Operators

- When you define operators for a class, you can write them either as **class methods** (object-oriented programming style) or as **free functions** (procedural programming style). Each style has its own advantages and disadvantages.
 - Defining an operator as a **class method** means that the operator is part of the class and therefore has **free access** to the **private** instance variables and other methods. But when you use this style to overload a binary operator, **the left operand is the receiver object** and the right operand is passed as a parameter.
 - Defining an operator as a **free function** often produces code that is **easier to read** (the operands for a binary operator are both passed as parameters as usual), but also means that the operator function must be designated as a **friend** to refer to the private data that do not have public getters.

Another Operator Overloading

- Say, we would like to implement addition to our Point class.
 1. Add a new method
 - Ex: `p1.add(p2)`
 2. Overload operator+ locally (as method)
 - `p1 = p1 + p2`, `p1 += p2`
 3. Overload operator+ globally

```
Point add(const Point & p) {  
    return Point { x+p.getX(), y+p.getY() };  
}
```

```
Point operator+(const Point & p) {  
    cout << __PRETTY_FUNCTION__ << endl;  
    return Point { x+p.getX(), y+p.getY() };  
}
```

Methods

```
Point & operator+=(const Point & p) {  
    this->x += p.getX();  
    this->y += p.getY();  
    return *this;  
}
```

Global

```
Point operator+(const Point & p1, const Point & p2) {  
    cout << __PRETTY_FUNCTION__ << endl;  
    auto ret {p1};  
    ret += p2;  
    return ret;  
    // return Point { p1.getX()+p2.getX(), p1.getY()+p2.getY() };  
}
```

Other numeric operator

```
Point & operator-=(const Point & p) {  
    this->x -= p.getX();  
    this->y -= p.getY();  
    return *this;  
}
```

```
Point & operator*=(int s) {  
    this->x *= s;  
    this->y *= s;  
    return *this;  
}
```

Comparison Operators

- Based on magnitude of the points

```
double magnitude(double x, double y) {  
    |   return sqrt(x*x + y*y);  
}
```

- ```
cout << boolalpha << "p1 == p2 " << (p1==p2) << endl;
cout << boolalpha << "p1 > p2 " << (p1>p2) << endl;
cout << boolalpha << "p3 > p1 " << (p3>p1) << endl;
cout << boolalpha << "p3 >= p1 " << (p3>=p1) << endl;
cout << boolalpha << "p4 == p5 " << (p4==p5) << endl;
cout << boolalpha << "p4 >= p5 " << (p4>=p5) << endl;
cout << boolalpha << "p4 <= p5 " << (p4<=p5) << endl;
cout << boolalpha << "p4 < p5 " << (p4<p5) << endl;
```

# Implementation (==, <)

Global

```
// comparison operators
bool operator==(Point p1, Point p2) {
 return p1.getX() == p2.getX() && p1.getY() == p2.getY();
}

bool operator<(const Point & p1, const Point & p2) {
 return !(fabs(p1.mag-p2.mag) < 0.0001f) && p1.mag < p2.mag;
 // return p1.mag < p2.mag; // this will not work 100%
}
```

```
// To allow the following external functions to access the private
friend bool operator<(const Point & p1, const Point & p2);
```

# Other comparison operators

- In fact, we can implement  $\leq$ ,  $\geq$ ,  $\neq$ ,  $>$  in terms of  $==$  and  $<$
- $p1 \neq p2$  is  $!(p1 == p2)$
- $p1 \leq p2$  is  $(p1 < p2) \parallel (p1 == p2)$
- $p1 \geq p2$  is  $!(p1 < p2)$
- $p1 > p2$  is  $(p2 < p1) \&\& !(p1 == p2)$

```
// express <=, >=, >, != in terms of == and <
bool operator!=(Point p1, Point p2) {
| return !(p1 == p2);
| }

bool operator<=(const Point & p1, const Point & p2) {
| return (p1<p2) || (p1==p2);
| }

bool operator>=(const Point & p1, const Point & p2) {
| return !(p1<p2);
| }

bool operator>(const Point & p1, const Point & p2) {
| return (p2<p1) && !(p1==p2);
| }
}
```

# A Strategy for Defining New Classes

- **Think generally** about how clients are likely to use the class.
- Determine what information belongs in the **private state** of each object.
- Define a set of **constructors** to create new objects.
- Enumerate the operations (including the overloaded functions and operators) that will become the **public methods** of the class.
- If necessary, define **free functions** that can manipulate the objects outside the class definition, but make them **friends** to the class.
- **Code** (as the implementer) and **test** (as the client) the implementation.
- Keeping implementation details away from the client is likely to foster *simplicity*, *flexibility*, and *security*, as described in the previous lectures (compare this to libraries).

# Example: Rational Numbers

- As a more elaborate example of class definition, section 6.3 defines a class called **Rational** that represents *rational numbers*, which are simply *the quotient of two integers*.
- Rational numbers can be useful in cases in which you need exact calculation with fractions (e.g.,  $1/3 = 0.\dot{3}$ ).
- Even if you think  $1/10 = 0.1$  is exact, when you use a **double**, 0.1 is represented internally as an approximation ([Why 0.1 Does Not Exist In Floating-Point?](#)).
- Rational numbers support the standard arithmetic operations:

Addition:

$$\frac{a}{b} + \frac{c}{d} = \frac{ad + bc}{bd}$$

Subtraction:

$$\frac{a}{b} - \frac{c}{d} = \frac{ad - bc}{bd}$$

Multiplication:

$$\frac{a}{b} \times \frac{c}{d} = \frac{ac}{bd}$$

Division:

$$\frac{a}{b} \div \frac{c}{d} = \frac{ad}{bc}$$

# Implementing the **Rational** Class

- The private instance variables: *numerator* and *denominator*.
- The *constructors* for the class are overloaded. Calling the constructor with **no argument** creates a **Rational** initialized to 0, calling it with **one argument** creates a **Rational** equal to that integer, and calling it with **two arguments** creates a fraction. The following properties should be enforced: (why?)
  - The fraction is always expressed in **lowest term**.
  - The denominator is always positive.
  - The rational number 0 is always represented as the fraction 0/1.

Since these values never change once a new **Rational** is created, these properties will remain in force.

- The class overloads the **standard arithmetic operations** ( **+** , **-** , **\*** , **/** ) to allow the use of conventional mathematical notation.

# The `rational.h` Interface

```
/*
 * File: rational.h
 * -----
 * This interface exports a class representing rational numbers.
 */

#ifndef _rational_h
#define _rational_h

```

```
/* Function prototypes */
```

```
int gcd(int x, int y);
```

```
/* Constructors */
```

*Why is the prototype of `gcd` not in `rational.h` or the `Rational` class definition?*

# The `rational.cpp` Implementation

```
Rational::Rational() {
 num = 0;
 den = 1;
}

Rational::Rational(int n) {
 num = n;
 den = 1;
}

Rational::Rational(int x, int y) {
 if (x == 0) {
 num = 0;
 den = 1;
 } else {
 int g = gcd(abs(x), abs(y));
 num = x / g;
 den = abs(y) / g;
 if (y < 0) num = -num;
 }
}
```

# The `rational.cpp` Implementation

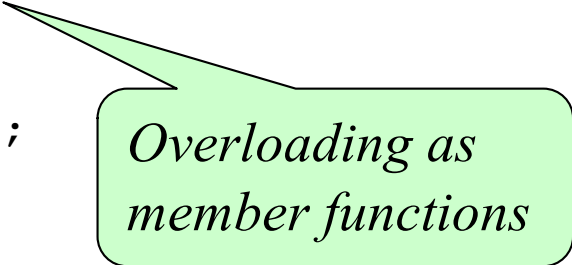

```
/* Implementation of the arithmetic operators */
```

```
Rational Rational::operator+(Rational r2) {
 return Rational(num * r2.den + r2.num * den, den * r2.den);
}
```

```
Rational Rational::operator-(Rational r2) {
 return Rational(num * r2.den - r2.num * den, den * r2.den);
}
```

```
Rational Rational::operator*(Rational r2) {
 return Rational(num * r2.num, den * r2.den);
}
```

```
Rational Rational::operator/(Rational r2) {
 return Rational(num * r2.den, den * r2.num);
}
```

*Overloading as  
member functions*

# The `rational.cpp` Implementation

```
string Rational::toString() {
 if (den == 1) {
 return integerToString(num);
 } else {
 return integerToString(num) + "/" + integerToString(den);
 }
}

int gcd(int x, int y) {
 int r = x % y;
 while (r != 0) {
 x = y;
 y = r;
 r = x % y;
 }
 return y;
}

ostream & operator<<(ostream & os, Rational rat) {
 os << rat.toString();
 return os;
}
```

# Exercise: overloading as free functions?

```
// in rational.h, inside the class Rational definition
friend Rational operator+(Rational r1, Rational r2);
friend Rational operator-(Rational r1, Rational r2);
friend Rational operator*(Rational r1, Rational r2);

 return Rational(r1.num * r2.den - r2.num * r1.den, r1.den * r2.den);
}
Rational operator*(Rational r1, Rational r2) {
 return Rational(r1.num * r2.num, r1.den * r2.den);
}
Rational operator/(Rational r1, Rational r2) {
 return Rational(r1.num * r2.den, r1.den * r2.num);
}
```

# Designing a token scanner class

- Many applications need to divide a string into words, or more generally, into logical units that may be larger than a single character. In computer science, such units are typically called *tokens*.
- Different applications, however, define tokens in all sorts of different ways, which means that the **TokenScanner** class must give the client some control over what types of tokens are recognized. E.g., the following line of text can be scanned into many different possible sequences of tokens.

```
cout << "hello, world" << endl;
```

- The Stanford C++ library includes a **TokenScanner** class that offers considerable flexibility without sacrificing simplicity.

# Designing a token scanner class

- From the client's point of view:

```
Set the input for the token scanner to be some string or input stream.
while (more tokens are available) {
 Read the next token.
 Perform other operations using the token.
}
```

- From the implementer's point of view:
  - A **setInput** method that allows clients to specify the token source, ideally, overloaded to take either a string or an input stream.
  - A **hasMoreTokens** method that tests whether the token scanner has any tokens left to process.
  - A **nextToken** method that scans and returns the next token.

## TUTORIAL

# Methods in the TokenScanner Class

**scanner.setInput(str)** *or* **scanner.setInput(infile)**  
Sets the input for this scanner to the specified string or input stream.

**scanner.hasMoreTokens()**

Returns **true** if more tokens exist, and **false** at the end of the token stream.

**scanner.nextToken()**

Returns the next token from the token stream, and "" at the end.

**scanner.saveToken(token)**

Saves **token** so that it will be read again on the next call to **nextToken**.

**scanner.ignoreWhitespace()**

Tells the scanner to ignore whitespace characters.

**scanner.scanNumbers()**

Tells the scanner to treat numbers as single tokens.

**scanner.scanStrings()**

Tells the scanner to treat quoted strings as single tokens.

# Encapsulating Programs as Classes

- Particularly as programs grow larger and more complex, it is often useful to construct an object that represents the program, as opposed to writing the code directly inside the **main** function. Doing so has several advantages, including making it possible to associate instance variables with the program.
- The text uses a revised version of the checkout-line simulation from Chapter 5 to illustrate this technique. The original **main** method has the following form:

```
int main() {
 int nServed;
 int totalWait;
 int totalLength;
 runSimulation(nServed, totalWait, totalLength);
 printReport(nServed, totalWait, totalLength);
 return 0;
}
```

# Encapsulating Programs as Classes

- After encapsulating the code in a class called **CheckoutLineSimulation**, and the **main** method has the following form:

```
class CheckoutLineSimulation {
public:
 void runSimulation() {...}
 void printReport() {...}
private:
 int nServed;
 int totalWait;
 int totalLength;
};

int main() {
 CheckoutLineSimulation simulation;
 simulation.runSimulation();
 simulation.printReport();
 return 0;
}
```

# Encapsulating Programs as Classes

- The primary advantage of doing so is that classes provide better encapsulation. The fact that access to any private data is limited to the class itself means that **it is much safer to use private instance variables to share information than it is to use global variables**, which offer no such security.
- The information shared between these functions can now be **stored in instance variables** and need not be **passed as arguments**. Being able to share access to such data among all the methods in the class substantially reduces the size and complexity of the parameter lists.

# A Note on Object-Oriented Programming

- *Encapsulation, Polymorphism, and Inheritance.*
- As you may know from other object-oriented languages such as Python, classes form hierarchies in which subclasses inherit the behavior and representation of their superclass. *Inheritance* also applies in C++, although the model is more complex, primarily because C++ allows classes to inherit from more than one superclass. This property is called multiple inheritance.
- Partly because of this additional complexity and partly because C++ makes inheritance harder to use, we postpone the discussion of inheritance until later in the lectures, focusing instead on the use of classes for *encapsulation*.
- We have also touched upon *polymorphism* by showing you some examples of function/operator overloading. We will discuss it more when we learn about template later.

| Class                                                                                                                       | Prototype                                                                                                                                                                             |
|-----------------------------------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Class and instance are distinct entities.                                                                                   | All objects can inherit from another object.                                                                                                                                          |
| Define a class with a class definition;<br>instantiate a class with constructor methods.                                    | Define and create a set of objects with<br>constructor functions.                                                                                                                     |
| Create a single object with the new<br>operator.                                                                            | Same.                                                                                                                                                                                 |
| Construct an object hierarchy by using class<br>definitions to define subclasses of existing<br>classes.                    | Construct an object hierarchy by assigning<br>an object as the prototype associated with a<br>constructor function.                                                                   |
| Inherit properties by following the class<br>chain.                                                                         | Inherit properties by following the<br>prototype chain.                                                                                                                               |
| Class definition specifies all properties of<br>all instances of a class. Cannot add<br>properties dynamically at run time. | Constructor function or prototype specifies<br>an initial set of properties. Can add or<br>remove properties dynamically to<br>individual objects or to the entire set of<br>objects. |

The End
